ABSTRACT

In this paper we briefly review the main hypotheses and extrapolations used to predict the observability of new heavy flavours at the CERN (p̅p) Collider. Some results from this study are compared with the first experimental data on the production of high-\(p_T\) electrons accompanied by hadronic "jets" at the (p̅p) Collider, as observed by the UA1 Collaboration. These events could, in fact, be the signature of the semileptonic decay of a very massive, new heavy-flavoured state. Its "down-like" or "up-like" nature cannot be established in a direct and unambiguous way. More sophisticated measurements are needed, as discussed in detail in a previous paper.

(Submitted to Nuovo Cimento Letters)
1. INTRODUCTION

We have already emphasized the important role that the CERN (pP) Collider might have as a machine to produce very heavy flavours\(^1\). So far, in the (pP) Collider exploitation the emphasis has been concentrated on the search for the intermediate vector bosons \(W^\pm\) and \(Z^0\). However, the discovery of these theoretically expected particles sheds no light on either of the two crucial and totally unresolved problems of subnuclear physics: the family and the hierarchy.

This is why more attention should be devoted to the problem of what the (pP) Collider could do in the heavy-flavour domain. In fact, the search for new flavours compares very well with the physics of the electroweak gauge bosons.

We have already discussed in detail\(^1\) a method of detecting new heavy flavours, with a direct and unambiguous identification of their "up-like" or "down-like" nature, via the \((e^+/e^-)\) asymmetry measurement.

Here, we propose an approach to the heavy flavours at the (pP) Collider which shows the importance of the asymmetry method. This approach is based on known facts and on a few simple hypotheses. Facts and hypotheses are then extrapolated to (pP) Collider energies.

Our estimates are compared with the UA1 data\(^2\), i.e. their 11 events showing an isolated \((e^\pm)\) accompanied by a hadronic jet.

2. THE FACTS

The facts are that:

1) the heavy flavours \(A^+_c\) and \(A^0_b\) are produced at ISR energies in a "leading" way\(^3\), i.e.
\[
\frac{d\sigma}{dx} \propto (1 - x)\alpha ,
\]
with \(\alpha \sim 1\);

2) the "heavy" quark masses are in the following ratios\(^4\):
\[ \frac{m_c}{m_s} = 3.5 \] \tag{2a}

\[ \frac{m_b}{m_s} = 11 \] \tag{3a}

3) there are good reasons to believe \(^4\) that the "strange" quark mass \( m_s \) is heavy enough to behave like a heavy flavour, such as "charm" and "beauty";

4) the cross-sections for the heavy flavours, "strange" (s), "charm" (c), and "beauty" (b), are measured up to the ISR energies, even if with large uncertainties (c and b);

5) all generalized Cabibbo angles, measured so far, are either small or compatible with being small.

3. THE HYPOTHESES

The hypotheses are:

1) \[ \frac{m_c}{m_s} = m(\text{up-like})/m(\text{down-like}) \] \tag{2b}

2) \[ \frac{m_b}{m_s} = m(\text{family N+1})/m(\text{family N}) \] \tag{3b}

3a) the cross-sections for production of heavy flavours are mainly dictated by dimensionality and scaling:

dimensionality says:

\[ \sigma = \left( \frac{1}{m_s^2} \right) \]

scaling says:

\[ \sigma = f(\sqrt{s}/m_s) \]
therefore:

\[ \sigma = \left( \frac{1}{m_f} \right)^2 f(\sqrt{s}/m_f) \]  \hspace{1cm} (4)

which means that the knowledge of the cross-section for the production of a heavy flavour having mass \( m_i \) at energy \( \sqrt{s}_i \) allows us to know the cross-section of a heavier flavour having mass \( m_j \) at the scaled energy \( \sqrt{s}_j \), according to:

\[ \sigma_j[\sqrt{s}_j = (m_j/m_i) \times \sqrt{s}_i] = \sigma_i[\sqrt{s}_i] \times (m_i/m_j)^2 \]  \hspace{1cm} (5)

3b) the cross-sections for heavy-flavour production can be predicted by QCD\(^5\);

4) the generalized Cabibbo angles, even those coming from the existence of the 4th family, are small, and the "flavour changing" neutral currents are forbidden to any order of family. The amplitude for a transition from family N to family \((N \pm \alpha)\) has a coefficient:

\[ \Pi \sin \theta_{i_i} \]  \hspace{1cm} \( \alpha = 1, \alpha \)

this implies that the dominant transitions are those between neighbouring families.

4. THE EXTRAPOLATIONS

The extrapolations are:

1a) the "leading" phenomenon holds for the production of heavy flavours at the Collider energies;

1b) the "leading" phenomenon is also present in the decay of the heavy-flavoured states;
2) \[ \frac{m_c}{m_s} \approx 3.5 \approx \frac{m(\text{up-like})}{m(\text{down-like})} = 4 ; \]

3) \[ \frac{m_b}{m_s} \approx 11 \approx \frac{m(\text{family N+1})}{m(\text{family N})} = 11 ; \]

4a) the cross-sections measured for "s" and "c" at lower energies can be extrapolated to the (p\bar{p}) Collider energy, using formula (5);

4b) the cross-sections calculated using QCD\(^5\) can be extrapolated, using formula (5), to very heavy masses at the (p\bar{p}) Collider energies.

5. THE CONSEQUENCES

The consequences are the following.

1a) The "leading" phenomenon in the production of heavy flavoured states at the (p\bar{p}) Collider produces an \((e^+ / e^-)\) asymmetry which changes sign from the proton to the antiproton hemisphere and is \((e^+ / e^-)\) energy-dependent. Notice that the asymmetry method allows the "up-like" or "down-like" nature of the new heavy flavours to be distinguished in a direct way. This effect has already been discussed in detail elsewhere\(^1\).

1b) The "leading" phenomenon in the semileptonic decay of a heavy-flavoured state, produces a very specific pattern: the heavy-quark side of the decay state has a depressed "hadronization" and it recoils against the weak intermediate boson, i.e. against the (ev) pair.

2) The mass of the "top" quark is expected to be in the 25 GeV/c\(^2\) range. This mass value is important because it determines the energy available in the decay from a heavier quark.

3) The mass of the first member of the 4th family, "down-like" (called "superbeauty")\(^1\), is in the 55 GeV/c\(^2\) range. We will therefore take \(\Delta m \approx 30\) GeV/c\(^2\) as the typical mass difference in the decay of "superbeauty" into "top".
4) The values of the cross-sections for "top" and "superbeauty" are
given respectively in Figs. 1a and b as extrapolations from "s" and
from "c". It is interesting to note that these two ways of getting
cross-section information in the (p$\bar{p}$) Collider range are not in vi-
olent disagreement. Furthermore, the QCD expectation is within the
"charm" extrapolated range of uncertainty in the "superbeauty" case.

6. COMPARISON WITH PRELIMINARY DATA FROM THE CERN (p$\bar{p}$) COLLIDER

As a first step in the study of the heavy-quark physics using the (p$\bar{p}$)
Collider, we propose to compare our predictions with the data already
available from the (p$\bar{p}$) Collider.

In their search for electron candidates, the UA1 Collaboration finds 16
events with an isolated electron\textsuperscript{2).} Five of these events are attributed to
$W^\pm$ decay, whilst the remaining 11 are characterized by a "jet activity" in
the azimuthal region opposite the isolated electron. The events correspond
to a total integrated luminosity of $L = 20 \text{ nb}^{-1}$.

According to the Monte Carlo discussed in detail in a previous paper\textsuperscript{1)},
the acceptance for electrons originating from "superbeauty" decays in the
phase space region defined by the UA1 data ($p_T > 15 \text{ GeV/c}$ and, for the
polar angle, $25^\circ < \theta < 155^\circ$) is, for baryon and antibaryon decays,

$$\varepsilon_B(e^\pm) = 0.08,$$

and for meson and antimeson decays,

$$\varepsilon_M(e^\pm) = 0.12.$$

We can therefore use the approximation

$$\varepsilon(e^\pm) = \varepsilon_B(e^\pm) = \varepsilon_M(e^\pm) = 0.1.$$

Since the heavy flavours are produced in pairs, the total efficiency for
seeing at least one electron from the leptonic decay of "superbeauty" is
\[ \varepsilon_T(\pm) = 2 \times \varepsilon(\pm) = 0.2 , \]

where we have assumed equal semileptonic branching ratios for baryon and meson decays.

The request for "jet activity" opposite in azimuth to the electron, gives rise to another acceptance factor, \( \varepsilon_T(\text{jet}) \), which we can derive by analysing the hadronic pattern of the "superbeauty" semileptonic decays predicted by our Monte Carlo, according to the "jet" definition outlined by the UA1 Collaboration, i.e.

i) all particles with \( p_T > 2.5 \text{ GeV/c} \) are associated with a jet if their separation in phase space is

\[ \Delta R = \sqrt{(\Delta \phi)^2 + (\Delta \eta)^2} < 1 , \]

with \( \Delta \phi \) in radians and \( \eta (=\ \text{pseudorapidity}) = -\ln (\tan \theta/2) \);

ii) all other particles are associated with the jet defined as in point (i), if they satisfy the conditions

\[ p_T \text{ relative to the jet} < 1 \text{ GeV/c}, \]
\[ \theta \text{ relative to the jet} < 45^\circ ; \]

iii) the total transverse energy of the jet must be greater than 10 GeV.

The result is

\[ \varepsilon_T(\text{jet}) \approx 70\% . \]

On the other hand, as shown in Fig. 2, the condition that the jet is opposite in azimuth to the electron within \( \Delta \phi = 30^\circ \) is nearly always satisfied.

The number of electrons from "superbeauty" semileptonic decays in the UA1 electron sample is therefore given by

\[ N(\pm) = \sigma_{sb} \times BR \times L \times \varepsilon_T(\pm) \times \varepsilon_T(\text{jet}) , \quad (6) \]

where \( BR \) is the semileptonic branching ratio of the "superbeauty" state\(^{1} \), taken to be \( BR = 0.15 \), and \( \sigma_{sb} \) is the cross-section for the production of
"superbeauty" particle states at the (p P) Collider; the other symbols have already been defined. The UA1 results show that \( N(e^+) = 11 \pm 3 \).

Note that in Eq. (6) the efficiencies for the electron trigger have not been taken into account. They are as follows:

i) The efficiency for detecting "isolated" electrons, i.e. with no other particles with \( p_T > 2 \text{ GeV/c} \) in a 20° cone around the electron direction. Here the risk is in the random vetoing, otherwise the efficiency for genuine events is very high. From UA1 data \(^2\) it is possible to deduce the upper limit for random vetoing: it must be below 75%, and it could, in fact, be almost zero.

ii) The efficiency of the energy cut \( E_T > 15 \text{ GeV/c} \) owing to the finite resolution of the electromagnetic shower detectors (EMSs). This efficiency can be evaluated to be > 95%, using the quoted EMSs energy resolution (\( \Delta E/E = 0.15\sqrt{E} \)).

Figure 3 shows the cross-section corresponding to the (11±3) events observed. Notice that the "experimental" finding of UA1 falls in a remarkable range of agreement with the crude extrapolations from "charm" and QCD.

Going further, we have compared the \( p_T \) distributions of the \( (e^+) \) from UA1 with that from our Monte Carlo simulation. This is shown in Fig. 4, where the Monte Carlo expectations are obtained using different values for the parameter \( b \) in the "superbeauty" production process

\[
\frac{d\sigma}{dp_T} \propto p_T \exp (-bp_T).
\]

Data and Monte Carlo distributions are normalized to the total number of events with \( p_T > 15 \text{ GeV/c} \).

A value of \( b = 0.20 \text{ GeV}^{-1}\text{c} \), i.e. a mean value for the production average transverse momentum \( \langle p_T \rangle \) of the order of 10 GeV/c, fits the UA1 data quite well. This value for \( b \) is much smaller than the value \( (b = 2.5) \) which we found in our study of "charm" production at the ISR \(^5\). However, it should be noticed that here we are dealing with the production of a flavour much heavier than "charm". The value \( b = 0.2 \) is in good agreement with the prescription \( \langle p_T^2 \rangle \approx m^2/4 \) (\( m \) is the quark mass) used by Odorico \(^5\) to compute.
the "charm" production properties from flavour excitation.

The efficiency for detecting electrons with $p_T > 15$ GeV/c in the Monte Carlo simulation does not change very much for $b > 0.2$, as shown in Fig. 5. Thus the total "superbeauty" cross-section derived by formula (6) holds, within $\pm 30\%$, even with this very low but expected value of $b$.

7. CONCLUSIONS

A sequence of arguments based on known facts and on simple hypotheses, extrapolated to the CERN (p$\bar{p}$) Collider energies, allow us to conclude that the (11$\pm$3) events observed by the UA1 Collaboration and consisting each of a single (e$^\pm$) accompanied by a jet activity in the opposite hemisphere, correspond to a value of the cross-section expected for the production of a very heavy flavoured state, in the 55 GeV/c$^2$ mass range. Moreover, the observed transverse momentum spectrum of the (e$^\pm$) follows the expectations for the semileptonic decay of a very massive state, again in the 55 GeV/c$^2$ mass range.

It should, however, be noticed that the identification of the "down-like" nature of the heavy-flavoured state is based on a series of hypotheses which produce the correct $\Delta m \approx 30$ GeV/c$^2$ for the (e$^\pm$) transverse momentum spectrum, and the correct magnitude for the cross-section. If we were to ignore the cross-section and the quark mass ratios which allow us to predict the masses of the 4th family, the only parameter left to fit the observed (e$^\pm$) transverse momentum spectrum would be the value $\Delta m \approx 30$ GeV/c$^2$. In this case the conservative interpretation of the UA1 results would be a "top" with a mass 30 GeV/c$^2$ above the "beauty".

This shows the importance of our proposal\(^1\) to study in detail the production of new heavy flavours at the CERN (p$\bar{p}$) Collider by measuring the (e$^+/e^-$) asymmetry. In fact, the sign of the asymmetry allows the identification of the "up-like" or "down-like" nature of the heavy-flavoured state in a direct and unambiguous way. Moreover, the (e$^+/e^-$) energy dependence of the asymmetry enables us to establish the correct sequence of

"down-like" $\Rightarrow$ "up-like"

decay chains for the new heavy flavours, and their mass difference.
