Recently we have proposed [1, 2] a general strategy for the analysis of precision
electroweak tests in view of the search for new physics beyond the Standard Model. Our
method is more complete and less model dependent than the similar approach based on the
variables S, T and U, [3–5] which, from the start, necessarily assumes dominance of
vacuum polarisation diagrams from new physics and truncation of the q^2 expansion of the
corresponding amplitudes. In a completely model independent way we define [1] four
variables, called E_{1}, E_{2}, E_{3} and E_{4}, that are precisely measured and can be compared with
the predictions of different theories. In the present note we apply our general approach to
the particularly interesting case of the Minimal Supersymmetric Standard Model (MSSM)
[6, 7]. Actually, since the MSSM is a completely specified, well defined and computable
theory one could imagine to directly compare the data with the predictions of the theory.
The problem is that the MSSM depends on many more unknown input parameters than the
Standard Model, so that a direct fitting procedure of the present data would not lead to a
significant determination of the individual parameters. Rather we will show that the
comparison of the experimental values of the epsilons with, on the one hand, the Standard
Model and, on the other hand, the MSSM, for the same values of the top quark mass m_t,
leads to very interesting indicative trends. In particular, we conclude that the MSSM is at
least in as good an agreement with the data as the Standard Model. Indeed the fit to
especially E_{3} and E_{4} becomes much better than for the Standard Model if some definite
and restrictive conditions on the spectrum of the MSSM are fulfilled.

The quantities e_{1}, e_{2}, e_{3} and e_{4} are defined in ref. 1 in one to one correspondence
with the set of observables m_{W}/m_{Z}, \Gamma_{t}, A_{FB} and \Gamma_{b}. The four epsilons are defined without
need of specifying m_{t}(and m_{3}). In the Standard Model, for all observables at the Z pole,
the whole dependence on m_{t} arising from one-loop diagrams only enters through the
epsilons. The same is true for any extension of the Standard Model such that all possible
deviations only occur through vacuum polarisation diagrams and/or the Z->b\bar{b} vertex. As
discussed in detail in ref. 1, for such a model one can compare the theoretical predictions
with the experimental determination of the epsilons as obtained from the whole set of LEP
data. If a model does not satisfy this requirement then the comparison is to be made with
the epsilons determined from the defining variables only, or with some more limited
enlargement of the same set, depending on the particular case (for example, if lepton
universality is maintained, then the data on A_{FB} can be replaced by the combined result on
\G_{\gamma}/\G_{\ell} from all lepton asymmetries). The epsilons are defined in such a way that they are
exactly zero in the Standard Model in the limit of neglecting all pure electroweak loop
corrections (i.e. when only the predictions from the tree level Standard Model plus pure
QED corrections are taken into account). Thus the epsilons represent an efficient
parameterisation of the small deviations from what is solidly established in a way that is
unaffected by our ignorance of m_{t}.

The MSSM is a well motivated extension [6] of the Standard Model. It provides the
possibility of a natural escape route from the worst aspects of the hierarchy problem [8]
while keeping fundamental scalar Higgses in the basic lagrangian. The measured values of

---

\(^{1}\) Here we resume the notation e_{i} for exactly the same quantities as defined in ref. 1, where they were
denoted \emph{eq}_{i}(the index \emph{N}, for "new", had been inserted to signal some small differences with respect to
the original definitions in ref.2).
the absence of observable proton decay and, to some extent, the observed value of $m_\text{Higgs}$ provide some empirical support [9] for supersymmetric SU(5) GUTs [10] as opposed to ordinary SU(5) [11]. The MSSM is a consistent perturbative theory, just as the Standard Model with a not too heavy Higgs, so the predictions for precision electroweak tests can be completely specified in terms of the, unfortunately numerous, input parameters of the theory. The MSSM is defined from the properties of generalizing the Standard Model with broken supersymmetry, of minimal particle content and of supersymmetry breaking being generated in a hidden sector and transmitted to standard matter by universal supergravity couplings [12]. In fact the additional requirement of R-parity conservation, which is usually assumed, does not play a great role in the present discussion. The MSSM has the same dimensionless couplings as the Standard Model except for one: the quartic Higgs self coupling is not a free parameter but is related to the gauge couplings. But there are five parameters with dimensions of mass in the MSSM, $m_1, m_2, m_3, \mu, m_0$, all of them being related to the scale of effective supersymmetry breaking (even the $\mu$ parameter which, in the low energy theory, appears in a supersymmetric term, may well originate, in a more complete theory, as a result of supersymmetry breaking, as many examples show). In the following, in order to simplify an otherwise inextricable complexity, we shall essentially concentrate on two limiting situations, denoted "heavy" MSSM and "light" MSSM. In the heavy case, we assume $m_1 > m_2$. Then the light spectrum of the MSSM is identical to that of the Standard Model with a light Higgs of mass smaller or comparable with the Z mass (as well known by now, the upper strict limit on the lightest Higgs mass critically depends on the top mass [13]). All the remaining particles predicted by the Standard Model can be made arbitrarily heavy, although at the price of an increasingly unnatural fine tuning which would progressively destroy one of the main motivations of the model, i.e. the understanding of the weak scale of mass. A crucial property of the MSSM is that the mass terms of the heavy particles are compatible with unbroken SU(2)$\times$U(1) symmetry. This property not only explains the observed light spectrum as the one formed by all the states whose mass is forbidden in the SU(2)$\times$U(1) symmetric limit, but also implies that the heavy particles decouple from radiative corrections (unlike the top quark in the Standard Model). For the electroweak precision tests the heavy MSSM tends to reproduce the predictions of the Standard Model with a light Higgs [14]. In the light MSSM option some of the superpartners have a relatively small mass, close to their experimental lower bounds. In this case the pattern of radiative corrections may sizably deviate from that of the Standard Model. The most interesting effects occur in vacuum polarisation amplitudes and/or the $Z\rightarrow b\bar{b}$ vertex and are particularly suitable for a description in terms of the epsilons (because in such a case, as explained in ref.1, the predictions can be compared to the experimental determination of the epsilons from the whole set of LEP data). They are:

i) a threshold effect in the Z wave function renormalisation [14] mostly due to the vector coupling of charginos and (off-diagonal) neutralinos to the Z itself. Defining the vacuum polarisation functions by $\Pi_{\mu\nu}(q^2) = ig_{\mu\nu} A(q^2) + i 2 T_{\mu\nu}(q^2) + i 4\phi_{\mu\nu}$, terms, this is a positive contribution to $\epsilon_{5}=\frac{m^2}{2}\frac{\phi_{ZZ}}{m^2_\text{Z}}$, the prime denoting a derivative with respect to $q^2$ (i.e. a contribution to a higher derivative term not included in the usual S,T,U formalism). The $\epsilon_5$ correction shifts $\epsilon_1$, $\epsilon_2$, $\epsilon_3$ by $-\epsilon_5$, $-\epsilon_5$ and $-\epsilon_5$ respectively, where $\epsilon_5=\frac{m^2}{2}\frac{\phi_{ZZ}}{m^2_\text{Z}}$, so that all of them are reduced by a comparable amount. Correspondingly all the Z widths are reduced without affecting the asymmetries. This effect can be significant but requires the lightest chargino to have a mass close to the experimental lower limit of 45 GeV.

ii) a positive contribution to $\epsilon_1$ from the virtual exchange of the scalar top and bottom superpartners [15], analogous to the contribution of the top-bottom quark doublet. The needed isospin splitting requires one of the two scalars (in the MSSM the s-top) to be light.

iii) a negative contribution to $\epsilon_2$, due to the virtual exchange of a charged Higgs [16]. If one defines, as customary, $tg\beta=\frac{v_1}{v_2}$ ($v_1$ and $v_2$ being the vacuum expectation values of the Higgs doublets giving masses to the down and up quarks, respectively), then, for negligible bottom Yukawa coupling or $tg\beta<\frac{m_3}{m_0}$, this contribution is proportional to $m_2^2/\tan^2\beta$.

iv) a positive contribution to $\epsilon_3$ due to virtual charged-s-top exchange [17] which, in this case is proportional to $m_2^2/\sin^2\beta$. This effect again requires the chargino and the s-top to be light in order to be sizeable.

All the above effects are cumulatively displayed in figs.1-4, where we give the pair correlations $\epsilon_1 - \epsilon_1$, $\epsilon_1 - \epsilon_2$, $\epsilon_1 - \epsilon_3$, $\epsilon_2 - \epsilon_3$ in the MSSM in the form of scatter plots. The ellipses are the 1 σ contours obtained from the present combined LEP experimental data (with the addition of the measurements of $m_{W}/m_{Z}$) [18]. The theoretical points in each plot are for fixed $m_{W}$=130 or 190 GeV. The Standard Model prediction as a function of $m_{W}$ is shown by two black stars corresponding to $m_{W}$=50 GeV and $m_{W}$=1000 GeV connected by a line. All Standard Model input parameters are fixed to the same values as in ref.1. In particular $\alpha(m_{Z})=(128.87 \pm 0.12)^{-1}$ [19] and $\epsilon_{5}(m_{Z})=0.118 \pm 0.007$ [20]. The MSSM scatter plot are obtained for $tg\beta>1$ (which is relevant to the effects described in iii) and iv) above), the charged Higgs mass $m_{H^\pm}>100$ GeV (relevant for iii) the lightest s-top and the approximately degenerate s-bottom masses (relevant to ii) and iv), $m_{H^\mp}=50$ GeV and $m_{H^\mp}=150$ GeV. This last constraint requires an additional qualification. In the mass matrix of the two top superpartners we limit the off diagonal term by taking $m_{t}<3m_{t_{\text{bottom}}}$, this constrains the relative s-top-s-bottom splitting when $m_{t_{\text{bottom}}}$ gets large and consequently the size of the effect on $\epsilon_1$: A particularly important role is played by the lightest chargino mass $m_{\chi^\pm}$, relevant to i) and iv). The white bullets refer to very light charginos: $60 < m_{\chi^\pm} < 48$ GeV, while the white stars, that by superposition from a dark area, refer to $m_{\chi^\pm} < 40$ GeV. The figures are actually realised by taking $tg\beta=1$ and $m_{H^\mp}=100$ GeV or $\approx$ (i.e. its contributions set to zero), $m_{H^\mp}=50$ or 200 GeV, $m_{H^\mp}=150$ GeV and varying the chargino masses in the mentioned ranges. The fact that only few representative values of $tg\beta$, $m_{H^\mp}$—plotted produces the filaments which are visible for light charginos. In this case the most important effects are those from $\epsilon_5$ and, if $m_{H^\mp}$ is also light, from $\epsilon_3$ via the mechanism iv) which strongly depends on $tg\beta$. For example, $\epsilon_5$, as already mentioned, gives proportional contributions to $\epsilon_1$, $\epsilon_2$ and $\epsilon_3$ and therefore produces lines in the planes of any two of those variables. The empty spaces between the lines would be filled up by taking intermediate values of the parameters.
In figs. 1-4 the dark area leans towards the heavy MSSM while the white bullets are from the light MSSM. At fixed $m_t$, the lowest values of $E_2$ and $E_3$, which are correlated, are obtained for a light chargino (note that the predicted value of $E_3$ is not larger in the MSSM than in the Standard Model); the lowest values of $E_1$ are realised for a light chargino and a heavy s-top; the largest values of $E_3$, for obtained for the chargino and the s-top both light, whereas, on the contrary, small values of $E_2$ require a light charged Higgs and small $t_{gB}$. As apparent from figs. 1-4, the differences between the theoretical predictions of the Standard Model and of the MSSM are not large in comparison with the present accuracy of the experiments, but they will become more important with the increase of statistics at LEP.

A defect of figs. 1-4 is that from them it is not clear that the same set of values of the parameters can simultaneously fit all four of the ellipses shown. This drawback is remedied in figs. 5-8 where for each $E_i (i=1,2,3,4)$ we plot two curves, as functions of $m_t$, and compare them with the data and with the Standard Model predictions. Both curves refer to the case of the light MSSM, where the effects are large, but with values of the parameters chosen in such a way as to approach the experimental data or to diverge from them. In figs. 5-8 all the curves that come close to the data (denoted as A) refer to $m_{t^*}=55$ GeV, $m_{h^*}=200$ GeV, while those that are far from the data (B) refer to $m_{t^*}=100$ GeV, $m_{h^*}=220$ GeV, which are the values of $m_{t^*}$ in both cases A and B, the values of $m_{t^*}$ are actually chosen so that $E_3$ is an extremum. For both sets of curves $t_{gB}=1$ and $m_{stop}=50$ GeV.

In the MSSM there is an upper limit on $m_t$ that arises from the existence of an infrared fixed point in the associated Yukawa coupling [21]. This limit reads $m_t < (150$ GeV $) \sin\beta$. Thus $150$ GeV is the maximum allowed value of $m_t$ in the MSSM (which is obtained for $t_{gB}$ large). As the upper limit on $m_t$ is derived from different physical assumptions than those that determine the pattern of radiative corrections at the weak scale, in figs. 1-8 we did not impose the constraints induced by the correlation between $t_{gB}$ and $m_t$, e.g. that $m_{t^*}<135$ GeV for $t_{gB}=1$. From figs. 1-8 we see that a value of $m_t$ as large as 190 GeV can actually be compatible with the data at about the 1σ level in the MSSM, if a light chargino is present.

In conclusion, the present precision electroweak data are well consistent with the MSSM. As the present data are very constraining this statement is highly non trivial. For example, simple technicolor models face serious problems [34,22]. In its heavy version, the pattern of radiative corrections predicted by the MSSM is practically indistinguishable from that obtained from the Standard Model with a light Higgs. The agreement with data improves considerably in the MSSM if a light gaugino and a light s-top exist, with masses close to their experimental bounds. The resulting effects can be important to bring $E_3$ and $E_4$ in closer agreement with the data. If this is the case then the gaugino and the s-top should be visible at LEP200.
