An upper limit on the branching ratio for $\tau$ decays into seven charged particles

The OPAL Collaboration

Abstract

We have searched for decays of the $\tau$ lepton into seven or more charged particles, using data collected with the OPAL detector from 1990 to 1995 in $e^+e^-$ collisions at $\sqrt{s} \approx M_\tau$. No candidate events were found and an upper limit on the branching ratio for $\tau$ decays into seven charged particles of $1.8 \times 10^{-5}$ at the 95% confidence level was determined.

1 Introduction

During the years 1990 to 1995 of LEP operation, an integrated luminosity of 163 pb\(^{-1}\) has been recorded with the OPAL detector at \(\sqrt{s} \approx 91\) GeV, corresponding to approximately five million observed \(Z^0\) decays. This large data sample, which contains more than 210000 \(\tau\) pair events, allows searches for rare decays of the \(\tau\) lepton with branching ratios down to about 10\(^{-5}\). The high-multiplicity decays of the \(\tau\) are particularly interesting for a measurement of the \(\tau\) neutrino mass. Recent examples of such measurements using \(\tau\) decays into three or five charged particles can be found in references [1, 2]. Taking only kinematical considerations into account, the decay of the \(\tau\) into twelve pions is possible.

In this note we present a search for \(\tau\) decays into seven charged particles (7-prong). The HRS Collaboration has published an upper limit of \(1 \times 10^{-4}\) on the branching ratio for \(\tau\) decays into seven charged particles\(^1\), \(BR (\tau^- \to 4\pi^- 3\pi^+ n\nu_\tau (n \geq 0))\), at the 90% confidence level [3]. The CLEO Collaboration has determined a 95% confidence level upper limit of \(1.1 \times 10^{-4}\) on the branching ratio \(BR (\tau^- \to 3\pi^- 2\pi^+ 2\pi^0 \nu_\tau)\) [4].

2 The OPAL detector

A detailed description of the OPAL detector can be found elsewhere [5]. Sub-detectors which are particularly relevant to the present analysis are described here briefly. The central detector consists of a system of tracking chambers providing charged particle tracking over 96% of the full solid angle inside a 0.435 T uniform magnetic field parallel to the beam axis\(^2\). Starting with the innermost components, it consists of a high precision silicon microvertex detector which was available from 1991, a precision vertex drift chamber, a large volume jet chamber with 159 layers of axial anode wires and a set of \(z\) chambers measuring the track coordinates along the beam direction. The efficiency for separating hits from two different particles in the jet chamber is approximately 80% for distances between two hits of 2.5 mm [6] and drops rapidly for smaller hit distances. The jet chamber also provides energy loss measurements which are used for particle identification.

A lead-glass electromagnetic calorimeter (ECAL) located outside the magnet coil covers the full azimuthal range with excellent hermeticity in the polar angle range of \(|\cos \theta| < 0.82\) for the barrel region and \(0.81 < |\cos \theta| < 0.984\) for the endcap region. The forward detectors and silicon tungsten calorimeters located at both sides of the interaction point measure the luminosity and complete the geometrical acceptance down to 24 mrad in polar angle.

3 Event simulation

The \(e^+e^- \to \tau^+\tau^-\) Monte Carlo events were generated using KORALZ 4.0 [7]. The dynamics of \(\tau\) decays to final states with five or fewer charged particles were simulated with the TAUOLA 2.4 decay library [8]. The 7-prong signal events were simulated by modifying the TAUOLA routine describing the decay of the \(\tau\) into five or more pions to allow up to seven charged pions with either zero \((\tau^- \to 4\pi^- 3\pi^+ \nu_\tau)\) or one neutral pions \((\tau^- \to 4\pi^- 3\pi^+ \pi^0 \nu_\tau)\) in the final state. To determine the efficiency for reconstructing an event with a 7-prong \(\tau\) decay we generated \(\tau\) pair events in which the first \(\tau\) decays according to the standard TAUOLA library and the second one decays into seven charged particles.

We have implemented various phase space models for these 7-prong decays. The standard case assumes an isotropic phase space between the minimum allowed value, equivalent to the sum of the pion masses, and the maximum allowed value, \(m_\tau\). To study the effect of the phase space modelling on the final result, we also considered the two extreme cases of a “low” and “high” phase space, that is with a 7-pion invariant mass always

\(^1\)References in this paper to specific charge states apply to the charge conjugate states as well.

\(^2\)The OPAL coordinate system is a right-handed coordinate system which is defined so that the \(z\)-axis is in the direction of the electron beam, the \(x\)-axis is horizontal and points towards the centre of the LEP ring; \(\theta\) and \(\phi\) are the polar and azimuthal angles, defined relative to the \(+z\)- and \(+x\)-axes, respectively.
below or above the value of $1.4 \text{ GeV/c}^2$, which is the mean value of $7m_\pi$ and $m_\tau$. Additionally, we generated 7-prong Monte Carlo events where the invariant mass of the 7-pion system is peaked close to this mean value in a Gaussian manner with a standard deviation of 150 MeV/c$^2$.

To estimate the background from $e^+e^-\rightarrow \tau^+\tau^-$ events with $\tau$ decays into up to five charged particles, we have used a sample of 920000 events generated with KORALZ and TAUOLA. The expected rate of multihadronic background was determined using $e^+e^-\rightarrow q\bar{q}$ events generated with JETSET [9]. The background coming from $e^+e^-\rightarrow e^+e^-$ events was estimated using a sample of simulated $e^+e^-\rightarrow e^+e^-$ events corresponding to a luminosity of 287 pb$^{-1}$ and generated with BABAMC [10]. Contributions from two-photon processes were studied using the PYTHIA [9] and Vermaseren [11] Monte Carlo generators. Background contributions coming from $e^+e^-\rightarrow \mu^+\mu^-$ and four-fermion events are small. They were investigated using the KORALZ and FERMISV [12] event generators, respectively.

All Monte Carlo events were passed through the GEANT [13] simulation of the OPAL detector [14] and were then processed in the same way as the real data.

4 Event preselection

A cone jet algorithm [15] was employed to assign all tracks and electromagnetic clusters to cones with a half opening angle of 35°. We required that exactly two cones with at least one track each were found in the event. Tracks were required to satisfy the following conditions:

- $p_\perp > 0.1 \text{ GeV/c}$, where $p_\perp$ is the momentum component transverse to the beam direction.
- A minimum number of 20 hits in the central jet chamber was required. This restricts the acceptance of the detector for tracks to $|\cos \theta| < 0.965$, where $\theta$ is the angle between the track and the beam axis.
- The distance of closest approach of the track to the beam axis must be less than 2 cm and the displacement of the track along the beam axis from the nominal interaction point at the point of closest approach to the beam must be less than 20 cm.

To reject events coming from two-photon interactions, the acollinearity of the two cones was required to be less than 15°, with the direction of each cone given by the momentum sum of all tracks and electromagnetic clusters inside the cone. The momenta of the ECAL clusters were calculated using the energy deposition and the angles of the cluster. The visible energy of each jet is taken as the maximum of the sum of the track momenta and the sum of the ECAL cluster energies associated with that jet. Events were rejected if the sum of the visible energies of the two jets was less than 3% of the centre-of-mass energy. Events with a total visible energy smaller than 20% of the centre-of-mass energy were rejected if the sum of the transverse momenta of the tracks and the sum of the transverse momenta of the electromagnetic clusters were both smaller than 2 GeV. This set of cuts rejects most of the two-photon background. Cosmic ray events were removed using the time-of-flight and the tracking chamber information [16]. Finally, we rejected events where some particles may be lost close to the beam pipe by requiring that the total energy deposit in the forward detectors be less than 2 GeV. We also required $|\cos \theta_{\text{cone}}| < 0.9$ for each of the two cones in the event, where $\theta_{\text{cone}}$ is the angle between the jet direction and the beam axis. This cut ensures that both jets are located inside the acceptance of the detector.

Only events with a minimum of four tracks were accepted for further analysis. The efficiency for selecting a $\tau^+\tau^-$ event with a 7-prong $\tau$ decay after the preselection cuts was $(80.8 \pm 0.5)\%$ according to the Monte Carlo simulation.

5 Selection of 7-prong $\tau$ events

At this stage, the largest sources of background, around 55%, come from $e^+e^-\rightarrow q\bar{q}$ events with a low-multiplicity jet, followed by $e^+e^-\rightarrow \tau^+\tau^-$ events with $\tau$ decays into five or fewer charged particles ($\approx 33\%$).
These backgrounds were reduced by the following set of cuts. Since approximately 99.9% of the \( \tau \) leptons decay into one or three charged particles, we required that the number of tracks \( N_1 \) in one of the two cones is exactly 1 or 3. The absolute value of the sum of the charges of these tracks was required to satisfy \(|\sum_{\text{tracks}} q| = 1\). The search for the 7-prong \( \tau \) decay was performed in the second cone. We required that this contains at least six tracks \((N_2 \geq 6)\) and that the absolute value of the sum of the track charges satisfies \(|\sum_{\text{tracks}} q| \leq 2\). The distribution of \( N_2 \) is shown in Figure 1.

The invariant mass of the tracks from a true 7-prong \( \tau \) decay must be less than the \( \tau \) mass. Therefore the invariant mass of the tracks in the second cone, \( m_2 \), calculated using the pion mass for each track, was required to satisfy \( m_2 \leq 1.6 \text{ GeV}/c^2 \) for cones with six reconstructed tracks and \( m_2 \leq 1.9 \text{ GeV}/c^2 \) for cones with \( N_2 \geq 7 \). The cut is lower for the \( N_2 = 6 \) case since the measured invariant mass of a true 7-prong decay candidate would be smaller due to the missing track. The distribution of \( m_2 \) before the cut is shown in Figure 2.

Most of the \( q\bar{q} \) events that were not removed by the invariant mass cut were rejected by a cut on the maximum opening angle of any pair of tracks in the two jets. For the first cone we required this angle to be less than \( 10^\circ \) \((\alpha_1^{\text{max}} < 10^\circ)\) when \( N_1 = 3 \). For the second cone we required \( \alpha_2^{\text{max}} < 8^\circ \). The distribution of \( \alpha_2^{\text{max}} \) is shown in Figure 2 for the data and for the signal and background Monte Carlo samples after the cuts on \( m_2 \) and \( \alpha_1^{\text{max}} \) have been applied.

Jets likely to contain one or more electrons coming from \( \tau \) decays with five or fewer tracks and additional tracks from photon conversions or \( \pi^0 \) Dalitz decays were rejected using the energy loss measurement and information on the energy deposit in the electromagnetic calorimeter. For the tracks in the 7-prong candidate cone we have calculated a quantity \( f_2 \), which is the logarithm of the ratio of the \( \chi^2 \) probability for the measured \( dE/dx \) of the track to be consistent with an electron to the probability for the measured \( dE/dx \) of the track to be consistent with a pion. If at least 20 \( dE/dx \) measurements along the specified track are available, we required \( f_2 \) to be less than 5. For the \( N_2 = 6 \) case this cut was lowered to \( f_2 < 3 \) to reject the conversion background more effectively. No cut was made for tracks with less than 20 \( dE/dx \) measurements or for tracks where both probabilities were smaller than 1%. The distributions of the maximum \( f_2 \) is shown in Figure 3. In this figure, the expected signal contribution is normalised assuming a branching ratio equal to the upper limit quoted in reference [3]. To reduce further the background from events containing electrons, we applied the additional cut \((E_{\text{cone}}/P_{\text{cone}}) < 0.8\), where \( E_{\text{cone}} \) is the sum of the energies of all electromagnetic clusters inside the cone and \( P_{\text{cone}} \) is the sum of the momenta of all tracks associated with the cone.

After all cuts, no event is found in the data. The expected number of background events from all modelled sources is \( 0.5^{+1.0}_{-0.3} \). The numbers of expected and observed events after each cut are shown in Table 1. The efficiencies for selecting a 7-prong \( \tau \) event are shown in Table 2 for the signal Monte Carlo samples described in section 3. A branching ratio equal to the upper limit quoted in reference [3] would result in approximately 33 \( \tau \) pair events containing a 7-prong \( \tau \) decay being observed in our data sample.

### 6 Systematic errors

The two sources of systematic errors in this analysis are the uncertainty in the total number of \( \tau \) pair events, \( N_{\tau+\tau^-} \), and the uncertainty in the 7-prong selection efficiency. We determined \( N_{\tau+\tau^-} \), using the total number of hadronic \( Z^0 \) decays and dividing by the ratio of the hadronic and the leptonic branching ratio of the \( Z^0 \) corrected for contributions from s-channel photon exchange. The calculated number of \( \tau \) pair events is \( N_{\tau+\tau^-} = 210680 \pm 1100 \). This corresponds to a systematic error of 0.5%.

For the determination of the upper limit on the branching ratio we chose the 7-prong Monte Carlo simulation with the isotropic phase space distribution of the 7-pion system. After all cuts we obtain a selection efficiency of 0.410 for this 7-prong Monte Carlo sample. Among all other 7-prong Monte Carlo simulations described in section 3, only the high phase space model leads to a lower final selection efficiency, which is still consistent with the selection efficiency for the isotropic phase space case. As an estimate of the systematic uncertainty from phase space effects, we therefore use the statistical error of the selection efficiency obtained for the isotropic 7-prong Monte Carlo sample, corresponding to a relative error of 3.9%.

---

3In the rest of the paper we refer to this as the first cone.
After applying the maximum measured $dE/dx$ of 10 keV/cm (electrons) and only unresolved double tracks should have a larger $dE/dx$ value. If at least one track has a momentum greater than 2 GeV/c and a $dE/dx$ value greater than 15 keV/cm was found, we conclude that this is due to two tracks that have not been resolved. After applying the preselection and the multiplicity cuts we calculated the fraction $f_{res}$ of 7-prong candidate cones in which such a high $dE/dx$ value was measured. We found that $f_{res}$ is about 2% smaller in the data than in the Monte Carlo simulation. This 2% discrepancy is also found in the low invariant mass region selected with $m_{\tau\tau} > 2$ GeV.

Relaxing the cut on $N_2$, we repeated this study for $N_2 = 4$ and $N_2 = 5$ and obtained similar results. Because a higher efficiency for the data than for the Monte Carlo simulation leads to a systematic error which does not affect the final limit, this effect has been neglected.

The uncertainty arising from the cut on the total charge of the cones was estimated by comparing the ratio of rejected events for data and Monte Carlo simulation when the cut is applied directly after the preselection and the multiplicity cuts, giving a relative uncertainty of 0.7%. For the invariant mass cut and the cut on the maximum angle between any pair of tracks, the systematic uncertainties were estimated by comparing data and Monte Carlo samples selected by requiring after the preselection $N_1 = 1$ and $5 \leq N_2 \leq 7$. The distribution of $m_2$ after applying these selection criteria is shown in Figure 4. For the two quantities, we obtain a combined relative systematic error of 1.1%. To determine the systematic uncertainties introduced by the cuts on $f_2$ and $(E_{cone}/P_{cone})_2$, we compared data and Monte Carlo samples selected by requiring after the preselection cuts $N_1 = 1$ and $N_2 \geq 6$ with an additional cut on the invariant mass in the second cone of $m_2 < 3$ GeV. For these samples, containing mostly $\tau$ pair events, a comparison of the $f_2$ and $(E_{cone}/P_{cone})_2$ distributions between data and the Monte Carlo simulation leads to 7-prong efficiency uncertainties of 0.6% and 1%, respectively. These results are also consistent with those obtained in [17].

Adding the systematic errors in quadrature, the total relative uncertainty of the 7-prong selection efficiency is 4.3% and is dominated by the uncertainty in the modelling of the 7-prong phase space.
### 7 Results

Using data collected with the OPAL detector at LEP at centre-of-mass energies on or near the Z\(^0\) resonance, we have searched for decays of the \(\tau\) lepton into seven or more charged particles. No candidate events were observed. An upper limit on the branching ratio is obtained using the calculated number of \(\tau\) pair events, \(N_{\tau^+\tau^-} = 210680 \pm 1100\), and the detection efficiency of \((41.0 \pm 1.8)\%\) according to

\[
BR (\tau^- \to 4\pi^- 3\pi^+ n\gamma \nu\tau (n \geq 0)) < \frac{3.0}{2 \cdot N_{\tau^+\tau^-} \cdot 0.410}.
\]  

(1)

The total relative systematic error of 4.3\% was included in the manner described in reference [18]. We obtain the upper limit on the branching ratio of

\[
BR (\tau^- \to 4\pi^- 3\pi^+ n\gamma \nu\tau (n \geq 0)) < 1.8 \times 10^{-5}
\]  

(2)

at the 95% confidence level. This is equivalent to an upper limit of \(1.4 \times 10^{-5}\) at the 90% confidence level. An improvement of more than one order of magnitude is achieved compared to the only previously published result [3].
